SUPO MEETING: 23rd Oct

↳ Pick the brightest and compare dispersion at the same velocity -> how repeatable is the ratios of brightness

- FWHM of lines to get velocity -> should be of order the same, but be aware of instrumental resolution.

[Lensing tools] -> thinking about this later, would come in useful when we know whether there is an excess of background tools

-> Interesting lensing / geometric effect, although we are amplifying sources, we could be zooming in on the background.

[Next steps] -> HST photometry -> what continuum brightness tends to looks

- Check that HST agrees with continuum level

If MUSE agrees with HST then quantify how much of the light is 'just' lines and not stars

Add HST/MUSE magnitude? Make sure we do some calibration with bright objects in the field -> not everything is made of stars!

Also worth checking the sky lines

-> Check the lines between NeII and Hδ

-> check from co-add whether balmer series is consistent.

-> Put on plot where we expect to see the Balmer continuum

- How much is Nebula continuum compared to stars.

Note: bump in continuum looks like cluster continuum contribution to

[?] Profound to make background map near source.

Make a plot of purely Balmer lines and also whether we have Balmer break on the spectrum -> coadd fixes this

$\boxed{\text{DS9}}$ to plot spectrum: select region and then plot 3D in analysis.
